We use a parametrized linear combination of atomic orbitals calculations to determine the stability, optimum geometry, and electronic properties of nanometer-sized capped graphitic cones, called ‘‘nanohorns.’’ Different nanohorn morphologies are considered, which differ in the relative location of the five terminating pentagons. Simulated scanning tunneling microscopy images of the various structures at different bias voltages reflect a net electron transfer towards the pentagon vertex sites. We find that the density of states at the tip, observable by scanning tunneling spectroscopy, can be used to discriminate between different tip structures.

Since their first discovery,¹ carbon nanotubes have drawn the attention of both scientists and engineers due to the large number of interesting new phenomena they exhibit,²,³ and due to their potential use in nanoscale devices: quantum wires,⁴ nonlinear electronic elements,⁵ transistors,⁶ molecular memory devices,⁷ and electron field emitters.⁸–¹² Even though nanotubes have not yet found commercially viable applications, projections indicate that this should occur in the very near future, with the advent of molecular electronics and further miniaturization of micro-electromechanical devices (MEMS). Among the most unique features of nanotubes are their electronic properties. It has been predicted that single-wall carbon nanotubes¹³,¹⁴ can be either metallic or semiconducting, depending on their diameter and chirality.¹⁶–¹⁸ Recently, the correlation between the chirality and conducting behavior of nanotubes has been confirmed by high resolution scanning tunneling microscopy (STM) studies.¹⁹,²⁰

Even though these studies have demonstrated that atomic resolution can be achieved,¹⁹–²¹ the precise determination of the atomic configuration, characterized by the chiral vector, diameter, distortion, and position of atomic defects, is still a very difficult task to achieve in nanotubes. Much of the difficulty arises from the fact that the electronic states at the Fermi level are only indirectly related to the atomic positions. Theoretical modeling of STM images has been found crucial to correctly interpret experimental data for graphite,²²,²³ and has been recently applied to carbon nanotubes.²⁴,²⁵ As an alternative technique, scanning tunneling spectroscopy combined with modeling has been used to investigate the effect of the terminating cap on the electronic structure of nanotubes.²⁶

Among the more unusual systems that have been synthesized in the past few years are cone-shaped graphite carbon structures.²⁷,²⁸ Whereas similar structures have been observed previously near the end of multiwall nanotubes,²⁹ it is only recently that an unusually high production rate of up to 10⁵ g/h has been achieved for single-walled cone-shaped structures, called “nanohorns,” using the CO₂ laser ablation technique at room temperature in absence of a metal catalyst.³⁰ These conical nanohorns have the unique opening angle of ≈20°.

We consider a microscopic understanding of the electronic and structural properties of nanohorns a crucial prerequisite for understanding the role of terminating caps in the physical behavior of contacts between nanotube-based nanodevices. So far, neither nanohorns nor other cone-shaped structures have been investigated theoretically. In the following, we study the structural stability of the various tip morphologies, and the interrelationship between the atomic arrangement and the electronic structure at the terminating cap, as well as the disintegration behavior of nanohorns at high temperatures.

Cones can be formed by cutting a wedge from planar graphite and connecting the exposed edges in a seamless manner. The opening angle of the wedge, called the disclination angle, is n(π/3), with 0 ≤ n ≤ 6. This disclination angle is related to the opening angle of the cone by θ = 2 sin⁻¹(1−n/6). Two-dimensional planar structures (e.g., a graphene sheet) are associated with n = 0, and one-dimensional cylindrical structures, such as the nanotubes, are described by n = 6. All other possible graphitic cone structures with 0 < n < 6 have been observed in a sample generated by pyrolysis of hydrocarbons.²⁸ According to Euler’s rule, the terminating cap of a cone with the disclination angle n(π/3) contains n pentagon(s) that substitute for the hexagonal rings of planar graphite.

The observed cone opening angle of ≈20°, corresponding to a 5π/3 disclination, implies that all nanohorns contain exactly five pentagons near the tip. We classify the structure of nanohorns by distinguishing the relative positions of the carbon pentagons at the apex which determine the morphology of the terminating cap. Our study will focus on the influence of the relative position of these five pentagons on the properties of nanohorns.

The cap morphologies investigated in this study are presented in Fig. 1. Nano-horns with all five pentagons at the ‘‘shoulder’’ of the cone, yielding a blunt tip, are shown in Figs. 1(a)–(c). Nanohorns with a pentagon at the apex of the tip, surrounded by the other four pentagons at the shoulder, are shown in Figs. 1(d)–(f). Note that the cone angle of each nanohorn is ≈20°, even though the size of the terminating cap varies with the relative position of the pentagons.

To determine the structural and electronic properties of carbon nanohorns, we used the parametrized linear combina-
tion of atomic orbitals (LCAO) technique with parameters determined by ab initio calculations for simpler structures.\(^\ref{31}\) This approach has been found useful to describe minute electronic structure and total energy differences for systems with unit cells that are too large to handle accurately by ab initio techniques.\(^\ref{32}\) Some of the problems tackled successfully by this technique are the electronic structure and superconducting properties of the doped C\(_{60}\) solid,\(^\ref{33}\) the opening of pseudogaps near the Fermi level in a (10,10) nanotubes rope,\(^\ref{34,35}\) and a (5,5)@(10,10) double-wall nanotube,\(^\ref{36}\) as well as fractional quantum conductance in nanotubes.\(^\ref{37}\) This technique, combined with the recursion technique to achieve an \(O(N)\) scaling, can determine very efficiently the forces on individual atoms,\(^\ref{38}\) and had previously been used with success to describe the disintegration dynamics of fullerenes,\(^\ref{39}\) the growth of multiwall nanotubes\(^\ref{40}\) and the dynamics of a ‘‘bucky-shuttle.’’\(^\ref{9}\)

To investigate the structural stability and electronic properties of carbon nanohorns, we first optimized the structures with various cap morphologies, shown in Fig. 1. For the sake of an easier interpretation of our results, we distinguish the \(N_{\text{cap}}\approx 40–50\) atoms at the terminating cap from those within the cone-shaped mantle, that is terminated by \(N_{\text{edge}}\) atoms at the other end. We associate the tip region of a hypothetically infinite nanohorn with all the sites excluding the edge. Structural details and the results of our stability calculations are presented in Table I. These results indicate that atoms in nanohorns are only \(\approx 0.1\) eV less stable than in graphite. The relative differences in \(\langle E_{\text{coh,tip}}\rangle\) reflect the strain energy changes induced by the different pentagon arrangements. To minimize the effect of under-coordinated atoms at the edge on the relative stabilities, we excluded the edge atoms from the average when calculating \(\langle E_{\text{coh,tip}}\rangle\). Since our results for \(\langle E_{\text{coh,tip}}\rangle\) and \(\langle E_{\text{coh,ed}}\rangle\) follow the same trends, we believe that the effect of edge atoms on the physical properties can be neglected for structures containing hundreds of atoms. Even though the total energy differences may appear minute on a per-atom basis, they translate into few electron-volts when related to the entire structure. Our results suggest that the under-coordinated edge atoms are all less stable than the cone mantle atoms by \(\approx 0.5\) eV. Also, atoms in pentagons are less stable than those in hexagons by \(\approx 0.1\) eV, resulting in an energy penalty of \(\approx 0.5\) eV to create a pentagon if the

FIG. 1. Optimized carbon nanohorn structures with a total disclination angle of \(5(\pi/3)\), containing five isolated pentagons at the terminating cap. Structures (a)–(c) contain all pentagons at the conical ‘‘shoulder,’’ whereas structures (d)–(f) contain a pentagon at the apex. The pentagons are highlighted by a darker color.

When comparing the stabilities of the tip regions, described by \(\langle E_{\text{coh,tip}}\rangle\), we found no large difference between blunt tips that have all the pentagons distributed along the cylinder mantle and pointed tips containing a pentagon at the apex. We found the structure shown in Fig. 1(c) to be more stable than the other blunt structures with no pentagon at the apex. Similarly, the structure shown in Fig. 1(e) is most stable among the pointed tips containing a pentagon at the apex. Equilibrium carbon-carbon bond lengths in the cap region are \(d_{\text{CC}} = 1.43 – 1.44\) Å at the pentagonal sites and \(d_{\text{CC}} = 1.39\) Å at the hexagonal sites, as compared to \(d_{\text{CC}} = 1.41 – 1.42\) Å in the mantle. This implies that the ‘‘single bonds’’ found in pentagons should be weaker than the ‘‘double bonds’’ connecting hexagonal sites, thus confirming our results in Table I and the analogous behavior in the \(C_{60}\) molecule.

Since pentagon sites are defects in an all-hexagon structure, they may carry a net charge.\(^\ref{41}\) To characterize the nature of the defect states associated with these sites, we calculated the electronic structure at the tip of the nanohorns. The charge density associated with states near \(E_F\), corresponding to the local density of states at that particular position and energy, is proportional to the current observed in STM experiments. To compute the local charge density associated with a given eigenstate, we projected that state onto a local atomic basis. The projection coefficients were used in conjunction with real-space atomic wave functions from density functional calculations\(^\ref{42}\) to determine the charge density corresponding to a particular level or the total charge density. To mimic a large structure, we convoluted the discrete level spectrum by a Gaussian with a full-width at half-maximum of 0.3 eV. Using this convoluted spectrum, we also determined the charge density associated with particular energy intervals corresponding to STM data for a given bias voltage.

In Fig. 2, we present such simulated STM images for the nanohorns represented in Figs. 1(c) and 1(d). We show the charge density associated with occupied states within a narrow energy interval of 0.2 eV below the Fermi level\(^\ref{43}\) as three-dimensional charge density contours, for the density value of \(\rho = 1.35 \times 10^{-3}\) electrons/Å\(^3\). Very similar results to
also calculated the density of states in the entire terminating cap, including all five pentagons and consisting of $N_{\text{cap}} \approx 40 \text{--} 50$ atoms, depending on the structure. The corresponding density of states, given by the solid line in Fig. 3, is vertically displaced for easier comparison. Our results show that the densities of states, both normalized per atom, are very similar. Thus, we conclude that the pentagonal sites determine all essential features of the electronic structure near the Fermi level at the tip. We note that a perturbation of the electronic structure far from defects has already been predicted in nanotubes.\(^{43}\)

In summary, we used a parametrized linear combination of atomic orbitals calculations to determine the stability, optimum geometry and electronic properties of nanometer-sized capped graphitic cones, called nanohorns. We considered different nanohorn morphologies that differ in the relative location of the five terminating pentagons. We found a net electron transfer to the pentagonal sites of the cap. This negative excess charge is seen in simulated scanning tunneling microscopy images of the various structures at different bias voltages. We found that the density of states at the tip, observable by scanning tunneling spectroscopy, can be used to discriminate between different tip structures.

We thank S. Iijima for fruitful discussions on carbon nanohorns. We acknowledge financial support by the Office of Naval Research and DARPA under Grant No. N00014-99-1-0252.

32 During structure optimization, we keep all sites charge neutral by modifying the diagonal elements of the Hamiltonian, to suppress structural artifacts near the edge. Once the geometry is optimized, the on-site energies are kept at the unperturbed values. Due to the absence of a Hubbard term, this procedure tends to exaggerate the net charge transfer when compared to truly self-consistent calculations.
42 The nanohorn structures considered in our calculation are clusters containing edge atoms. We found that due to the electron transfer towards the under-coordinated atoms at the edge, the ‘‘Fermi level’’ of these clusters may drop by as much as ~1.0–1.2 eV with respect to that of a graphene monolayer. To compensate for this artifact, we excluded the edge region from the calculated density of states and found the $E_F$ value to lie very close to that of a graphene monolayer.
