Supporting Information

ABSTRACT: We report a new strategy for fabricating 2D/2D low-resistance ohmic contacts for a variety of transition metal dichalcogenides (TMDs) using van der Waals assembly of substitutionally doped TMDs as drain/source contacts and TMDs with no intentional doping as channel materials. We demonstrate that few-layer WSe₂ field-effect transistors (FETs) with 2D/2D contacts exhibit low contact resistances of ~0.3 kΩ μm, high on/off ratios up to >10⁸, and high drive currents exceeding 320 μA μm⁻¹. These favorable characteristics are combined with a two-terminal field-effect hole mobility μFE ≈ 2 × 10² cm² V⁻¹ s⁻¹ at room temperature, which increases to >2 × 10³ cm² V⁻¹ s⁻¹ at cryogenic temperatures. We observe a similar performance also in MoS₂ and MoSe₂ FETs with 2D/2D drain and source contacts. The 2D/2D low-resistance ohmic contacts presented here represent a new device paradigm that overcomes a significant bottleneck in the performance of TMDs and a wide variety of other 2D materials as the channel materials in postsilicon electronics.

KEYWORDS: MoS₂, WSe₂, MoSe₂, field-effect transistor, two-dimensional, ohmic contact

The layered nature of transition metal dichalcogenides (TMDs) allows for easy cleavage and formation of ultrathin layers, which are being considered as suitable semiconducting counterparts to semimetallic graphene and may lead to flexible electronics and optoelectronics applications.¹⁻⁵ However, fabrication of high-performance transistors of TMDs including WSe₂, MoS₂, and MoSe₂ has been a major challenge in 2D electronics.⁶,⁷ The performance of current metal-contacted TMDs is limited by the presence of a significant Schottky barrier (SB) in most cases.⁸⁻¹² In silicon-based electronics, low-resistance ohmic contacts are achieved by selective ion implantation of drain/source regions below metal electrodes. In this way, the contact barrier width between the metal electrodes and degenerately doped source and drain regions is significantly reduced. Unfortunately, the ultrathin body of monolayer and few-layer TMDs prohibits effective doping by ion implantation. Various other doping methods such as surface charge transfer doping,⁶,¹³,¹⁴ and substitutional doping,¹⁶,¹⁷ have also been developed by different groups during the past few years to reduce the Schottky barrier width and thus reduce the contact resistance of TMD devices. However, most of these doping methods suffer from poor air or thermal or long-term stability. In this respect, substitutional doping appears to offer a suitable alternative, since dopants secured by covalent bonding (e.g., Nb doped MoS₂) during the material synthesis yield devices with excellent air and thermal stability.¹⁷ However, the limitation of conventional substitutional doping during synthesis is the inability to form a spatially abrupt doping profile, which defines the drain, the channel, and the source regions and which is needed for low power, high-performance electronics.

To date, various innovative strategies to reduce the contact resistance such as use of graphene contacts,⁵,¹⁸⁻²⁰ and phase-engineering,²¹,²² are still deficient as they do not offer true ohmic contact behavior or have insufficient thermal stability. Nearly barrier-free contacts to MoS₂ have been achieved by using graphene as contact electrodes because the Fermi level of graphene can be effectively tuned by a gate voltage to align with the conduction band minimum (CBM) of MoS₂, which minimizes the Schottky barrier height (SBH).²³⁻²⁵ Still, a significant SBH is usually formed between graphene and WSe₂ because the work function of graphene is close to the middle of the band gap in WSe₂.¹⁸,¹⁹ We have previously used the extremely large electric double layer (EDL) capacitance of an
ionic liquid (IL) gate to minimize the SBH by tuning the work function of graphene at the graphene/WSe2 interface within an extremely large range. As a result, we have formed for the first time, in a single device structure, WSe2-based FETs of both n- and p-type that display low-resistance contacts (down to $\sim$2 $\Omega \mu m$) and a high carrier mobility (>300 cm$^2$ V$^{-1}$ s$^{-1}$ at 77 K). However, for realistic device applications, methods to achieve more permanent, air-stable and thermally stable ohmic contacts with an order of magnitude lower contact-resistance are needed. Significant SBH reduction can also be achieved by locally inducing the metallic 1T phase MoS2 on semiconducting 2H phase MoS2 flake, which can be attributed to the atomically sharp interface between the 1T and 2H phases and to the fact that the work function of the 1T phase is very close to the CBM of the 2H phase. However, a finite SBH is expected to arise for the hole channel, when the work function of the 1T metallic phase does not line up with the CBM, and the hole channel, when the work function of the 1T phase does not line up with the valence band maximum (VBM) of the 2H phase. For instance, a large SBH is expected for the hole channel of degenerately p-doped MoS2 contacts formed for the 1T phase of MoS2 FETs using this phase-engineering contact strategy because of the large offset between the work function of the 1T phase and the VBM of the 2H phase. Furthermore, the 1T phase of MoS2 is thermally unstable above 100 °C. The availability of a variety of semiconducting TMDs such as MoSe2, WS2, and WSe2 with different band structures and charge neutrality levels offers additional distinct properties and opportunities for device applications. However, the variation of electron affinity, band gap, and band alignments also presents significant challenges to contact engineering. To unlock the full potential of TMDs as channel materials for high-performance thin-film transistors, highly effective and versatile contact strategies for making low-resistance ohmic contacts are needed.

In this Letter, we present a new strategy that utilizes 2D/2D vertical junctions to engineer low-resistance ohmic contacts, which turn TMDs including WSe2, MoS2, and MoSe2 into high-performance transistors. 2D/2D junctions with atomically sharp interfaces can be created by van der Waals assembly of 2D crystals without the constraints of atomic commensurability. We demonstrate that 2D/2D contacted FETs consisting of an undoped few-layer WSe2 channel and degenerately p-doped WSe2 drain and source contacts exhibit low contact resistances of $\sim$0.3 k$\Omega \mu m$, high on/off ratios up to $>10^5$, and high drive currents exceeding 320 $\mu A \mu m^{-1}$. Furthermore, low resistance ohmic contacts achieved in our devices enable the investigation of intrinsic channel properties of TMD materials. Our WSe2 devices with 2D/2D contacts display a two-terminal field-effect hole mobility $\mu_{FE}$ $\approx$ 2.2 $\times$ 10$^2$ cm$^2$ V$^{-1}$ s$^{-1}$ at room temperature, which increases to about 2.1 $\times$ 10$^3$ cm$^2$ V$^{-1}$ s$^{-1}$ at 5 K. Similarly, record high two-terminal field-effect hole mobility up to 2.8 $\times$ 10$^3$ cm$^2$ V$^{-1}$ s$^{-1}$ (at cryogenic temperatures) has been observed in MoS2 and MoSe2 FETs with degenerately p-doped MoS2 contacts formed by van der Waals assembly.

Figure 1a,b presents a schematic diagram and optical micrograph of a WSe2 FET device composed of degenerately p-doped WSe2 (Nb$_{0.005}$W$_{0.995}$Se$_2$) 2D drain/source electrodes in contact with a 2D WSe2 channel with no intentional doping. Devices containing TMDs such as WSe2 were fabricated by artificially stacking mechanically exfoliated flakes of degenerately p-doped TMDs, considered as electrodes, on top of an...
undoped TMD channel material using a dry transfer method. Subsequently, metal electrodes, consisting of 5 nm Ti/50 nm Au, were formed by deposition on top of the degenerately doped TMD contacts (see the Methods and Sections 1 and 2 of the Supporting Information). To preserve its intrinsic electronic properties, the TMD channel material was encapsulated in hexagonal boron nitride (hBN). Similar to degenerately doped silicon in Si electronics, ohmic contacts with low contact resistance <0.2 kΩ·μm is also achievable between degenerately doped TMDs and the top metal electrodes (see Section 3 of the Supporting Information). Consequently, the total contact resistance critically depends on the resistance of the 2D/2D junctions between the degenerately doped TMDs, acting as source/drain electrodes, and the undoped TMD channel material.

The band diagram and working principle of the 2D/2D contacts are illustrated in Figure 1c. The difference in work function between the undoped channel and the degenerately doped drain/source, caused by the different carrier densities, creates a band offset across the 2D/2D interface. In conventional 3D semiconductor junctions, the band offset is usually well-defined by the covalent bonds at the junction interface. Since the interlayer interaction in 2D TMDs and their junctions is much weaker, the band offset can be electrostatically tuned by a back-gate voltage. We take advantage of this unique property of 2D/2D junctions to form spatially sharp, tunable, true ohmic contacts to TMDs.

As seen in the top panel of Figure 1c, there are no free carriers in the channel in the off-state at the back-gate voltage $V_{bg} = 0$ V. Increasing the negative back-gate voltage shifts all bands in the channel material up, whereas the bands in the degenerately doped electrodes are unaffected. The modified band alignment introduces holes in the channel material, as illustrated in the bottom panel of Figure 1c. In the on-state, achieved at gate voltages exceeding the threshold ($|V_{bg}|>|V_{th}|$), the contact barrier at the interface essentially vanishes, leading to a low-resistance contact.

Figure 1d,e shows the room-temperature transfer and output characteristics of a five-layer WSe$_2$ FET that is encapsulated in hBN. This ∼3.5 nm thick device is contacted by degenerately p-doped WSe$_2$ (Nb$_{0.003}$W$_{0.997}$Se$_2$) and measured using a Si back gate. The gate dielectric consists of 40 nm thick hBN on 280 nm thick SiO$_2$. It shows clear p-type behavior with an exceptionally high on/off ratio exceeding 10$^5$ at $V_{ds} = -1$ V and a subthreshold swing of ∼460 mV/dec, which can be further reduced to the near-ideal value of ∼63 mV/dec by using a top gate with hBN gate dielectric (see Section 5 of the Supporting Information). The gate voltage range can also be significantly reduced by using thinner and high-k dielectrics. The high on/off ratio can be partially attributed to the significant enhancement of the on-current that is enabled by the low-resistance 2D/2D contacts. As shown in Figure 1e, the on-state drain current is linear at all back-gate voltages, indicating ohmic behavior. Although we present results on p-type TMD transistors in this work, we have also achieved n-type behavior using heavily n-doped TMDs as drain and source contacts (see Section 6 of the Supporting Information). This is an important advantage of the proposed 2D/2D contact strategy because availability of both p-type and n-type 2D transistors with low-resistance ohmic contacts is crucial for CMOS applications.

We quantify the contact resistances of the 2D/2D contacts using the transfer length method (TLM). Figure 2a,b shows the schematic diagram and an optical micrograph of a WSe$_2$ test structure for TLM measurements, consisting of an ∼7 nm thick undoped WSe$_2$ channel, outlined by the dash-dotted lines, and those of the Nb$_{0.005}$W$_{0.995}$Se$_2$ contacts by dashed lines. Ti/Au electrodes for electrical connections are deposited on top of the Nb$_{0.005}$W$_{0.995}$Se$_2$ contacts. The thickness of the WSe$_2$ channel is ∼7.0 nm. Scale bar, 1 μm. (c) Total resistance $R$ (multiplied by the channel width) versus channel length $L$. The intercept of the linear fit on the y-axis yields the contact resistance $2R_C$, (d) Output characteristics of the shortest channel ($L ∼ 0.27$ μm) in the TLM structure. The maximum current exceeds 320 μA/μm at $V_{ds} = -1.5$ V and $V_{bg} = -130$ V.
Figure 3. Observation of intrinsic channel properties in WSe2 (a,c) and MoS2 (b,d) devices with 2D/2D contacts. (a) Temperature-dependent two-terminal conductivity $\sigma$ of WSe2 as a function of the back-gate voltage $V_{bg}$ at $V_{ds} = -50$ V. The WSe2 channel is $\sim 3.5$ nm thick, 14.8 $\mu$m long and a 4.5 $\mu$m wide. Inset: temperature dependence of $\sigma$ at gate voltages ranging from $-30$ V to $-80$ V in steps of $-5$ V. A metal–insulator transition (MIT) is observed at $\sim e^2/h$ as indicated by the dashed line. (b) Temperature-dependent two-terminal conductivity $\sigma$ of MoS2 as a function of $V_{bg}$ at $V_{ds} = -10$ mV. The MoS2 channel is $\sim 6.8$ nm thick, 13.0 $\mu$m long, and a 2.5 $\mu$m wide. Inset: conductivity within the MIT region on an expanded scale. (c,d) Two-terminal field-effect hole mobilities $\mu_{fe}$ in WSe2 (c) and MoS2 (d) as a function of temperature. The maximum values observed in two-terminal measurements are $\mu_{fe} \approx 2.0 \times 10^3$ cm$^2$ V$^{-1}$ s$^{-1}$ in WSe2 and $\mu_{fe} \approx 2.8 \times 10^3$ cm$^2$ V$^{-1}$ s$^{-1}$ in MoS2 at cryogenic temperatures. The linearity of the output characteristics of WSe2 and MoS2 devices, shown in the insets of (c,d), indicates the absence of Schottky barriers in the contact region.

TLM measurements, shown in Figure 2b. The device exhibits large drive currents exceeding 320 $\mu$A $\mu$m$^{-1}$, which are comparable to the highest drive currents achieved in few-layer TMD devices. It is worth noting that even at the large values $V_{bg} = -130$ V and $V_{ds} = -1.5$ V, $I_{bg}$ has not yet reached saturation, which indicates that still higher drive currents should be achievable.

Low-resistance 2D/2D contacts also enable us to investigate the intrinsic properties of the channel. Figure 3a presents the temperature-dependent two-terminal conductivity of another WSe2 device that is 3.5 nm thick, $\approx 14.8$ $\mu$m long, $\approx 4.7$ $\mu$m wide, and passivated by hBN. The two-terminal conductivity is defined by $\sigma = I_{ds}/V_{ds} \times L/W$, where $L$ is the length and $W$ the width of the channel. With increasing hole concentration, the WSe2 device displays a crossover from an insulating regime, where the conductivity increases with increasing temperature, to a metallic regime, where the conductivity decreases with increasing temperature. This metal–insulator–transition (MIT) can be more clearly seen in the corresponding temperature-dependent conductivity curves in the metallic state at $-80$ V $< V_{bg} < -50$ V using the expression $\mu_{fe} = (1/C_{bg}) \times (dI_{ds}/dV_{bg})$, where $C_{bg}$ is the geometric back-gate capacitance of 27 nm thick hBN on 285 nm thick SiO2 based on the parallel plate capacitor model. This geometric capacitance is consistent with the back-gate capacitance of a similarly hBN-encapsulated WSe2 Hall bar device determined by Hall measurement (see Section 8 of the Supporting Information). As the temperature decreases from room temperature to 5 K, the hole mobility for the WSe2 device increases from $\sim 2.2 \times 10^3$ cm$^2$ V$^{-1}$ s$^{-1}$ to about $2.1 \times 10^3$ cm$^2$ V$^{-1}$ s$^{-1}$. This mobility increase with decreasing temperature, along with the large mobility values, suggests strongly that the hole transport in the device is limited by phonons in the channel.

Next, we demonstrate that the 2D/2D contact strategy can also be used to achieve low-resistance contacts for the hole channel of MoS2 FET devices, which has been a major challenge because hole injection across the metal/MoS2 interface has been obstructed by a large Schottky barrier. Figure 3b shows the two-terminal conductivity of an MoS2 FET device consisting of a 6.8 nm thick MoS2 channel with no intentional doping, contacted by degenerately p-doped MoS2 (Nb$_{0.005}$Mo$_{0.995}$S$_2$) drain and source electrodes. In contrast to MoS2 devices with conventional metal contacts, which overwhelmingly displays n-type behavior, the above MoS2 device exhibits p-type behavior. The temperature-dependent conductivity of the p-type MoS2 device also shows an MIT, as seen in the inset of Figure 3b. We observe an $\sim 13-$
conductivity $\sigma$ layer TMDs, which can be attributed to both low-

fraction increase of the on-state conductivity as the temperature decreases from 300 to 5 K and linear output characteristics
down to 5 K, depicted in the inset of Figure 3d, indicating a
barrier-free contact with a low contact resistance. The larger
negative threshold voltage observed in our p-type MoS$_2$ than in
p-type WSe$_2$ FETs can be attributed to the higher level of
intentional n-doping in the MoS$_2$ channel material. As seen in
Figure 3d, the field-effect hole mobility of the MoS$_2$ device
increases from $\sim1.8 \times 10^2 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ to about $2.8 \times 10^2 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ as the temperature decreases from room temperature to
5 K. To the best of our knowledge, the low-temperature mobility values observed in our p-type WSe$_2$ and MoS$_2$ devices
represent record high two-terminal hole mobility values in few-
layer TMDs, which can be attributed to both low-resistance 2D/2D ohmic contacts and hBN channel passivation.

To further demonstrate the versatility of the new contact
paradigm and to elucidate the nature of 2D/2D contacts, we
also investigated TMD devices with 2D/2D heterocontacts,
where the drain/source electrodes and the channel consist of
different TMD materials. Figure 4a,b presents the output
characteristics of representative devices consisting of an MoSe$_2$
channel and degenerately p-doped MoS$_2$ (Nb$_{0.005}$Mo$_{0.995}$S$_2$)
and WSe$_2$ (Nb$_{0.005}$W$_{0.995}$Se$_2$) drain/source contacts, measured
at 80 K. Whereas the MoSe$_2$ device in Figure 4a with p-doped
MoS$_2$ contacts shows linear output characteristics indicative of
ohmic behavior, the MoSe$_2$ device in Figure 4b with p-doped
WSe$_2$ contacts displays a strongly nonlinear behavior. The
nonlinearity and reduction of $V_{bg}$ suggest the presence of a
significant contact barrier in this case. Figure 4c,d presents
two-terminal conductivity as a function of gate voltage for the same
devices at different temperatures. The MoSe$_2$ device with p-
doped MoS$_2$ contacts exhibits a similar behavior as the WSe$_2$
and MoS$_2$ devices presented in Figure 3. This similarity
includes the presence of an MIT, an increase in on-state conductivity, measured at $V_{bg} = -100 \text{ V}$ and $V_{ds} = -10 \text{ mV}$, by a factor of $\sim19$ as the temperature decreases from 300 to 5 K. As seen in the inset of Figure 4c, the phonon-limited two-
terminal mobility increases from $\sim1.0 \times 10^2 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ at 300
K to about $2.4 \times 10^2 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ at 5 K. In sharp contrast, the
two-terminal conductivity in the MoSe$_2$ device with p-doped
WSe$_2$ drain/source contacts decreases rapidly as the temperature
decreases from 240 to 80 K, indicating contact-limited charge transport.

The drastically different behavior observed in devices with
2D/2D heterocontacts can be attributed to the differences in
band alignments between the channel and contact materials. In
the MoSe$_2$ directly underneath the drain/source contacts (region I in Figure 4e,f), the BVM of the MoSe$_2$ channel is
aligned to the BVM of the contact material (p-doped MoS$_2$
or p-doped WSe$_2$) by gate voltage when the channel is turned on,
leading to a vanishing contact barrier at the 2D/2D vertical
contact. However, this band alignment along the vertical
direction in region I creates a band offset along the lateral
direction parallel to the channel. Because the Fermi level in
the entire system must be the same in equilibrium, a local up-
turn occurs in the valence band in the lateral interface region,
called region II, in the case the BVM of the isolated MoSe$_2$
channel is above the VBM of the isolated p-doped MoS$_2$
drain/source contacts. This is accompanied by a flow of holes toward
the lateral interface region II, where the hole accumulation
builds up a local electric field that eventually prevents further charge redistribution. Because hole accumulation in region II does not hinder hole transport, ohmic behavior is observed. In the case where the VBM of the MoSe₂ channel is below the VBM of p-doped WS₂ drain/source contacts, a downward band bending occurs in the lateral interface region II, which is accompanied by a flow of holes away from this lateral interface region. The hole depletion in region II acts as a barrier hindering hole transport, leading to nonohmic behavior. We obtained consistent results in multiple p-type TMD FETs with 2D/2D heterocontacts: ohmic contacts are formed when the VBM of the channel material is above the VBM of the contact material and nonohmic behavior occurs when the VBM of the channel material is below that of the contact material. (see Sections 10 and 11 of the Supporting Information).

In summary, we have developed a novel 2D/2D contact strategy to achieve high-quality ohmic contacts for MoS₂, MoSe₂, and WSe₂ FETs. The low-resistance ohmic contacts lead to drastically improved device performance, including on/off ratios up to >10⁶, drive currents >320 μA μm⁻¹, and two-terminal extrinsic field-effect mobilities up to 2.8 × 10³ cm² V⁻¹ s⁻¹ at cryogenic temperatures. The newly developed contact engineering approach is applicable to a wide range of 2D materials for both p-type and n-type transistors, which are compatible with conventional semiconductor processes, and may be implemented in roll-by-roll production of flexible electronics with the development of large scale synthesis techniques.

Methods. All crystals of degenerately doped and undoped TMDs used in this work were synthesized by chemical vapor transport except for undoped MoS₂ crystals, which were purchased from SPI Supplies. Optical microscopy and Park-Systems XE-70 noncontact mode atomic microscopy (AFM) were used to identify and characterize thin TMD flakes.

To fabricate TMD devices with 2D/2D contacts, thin flakes of degenerately doped and undoped ultrathin TMDs were mechanically exfoliated from bulk crystals. The degenerately doped TMD flakes, forming the drain and source electrodes, were then artificially stacked using a dry transfer method on top of undoped TMDs flakes, which form the channel. Metal electrodes were then fabricated on top of the degenerately doped source and drain contact regions by standard electron beam lithography and subsequent deposition of 5 nm of Ti and 50 nm of Au (see also Section 2 of the Supporting Information).

Electrical properties of the devices were measured by a Keithley 4200 semiconductor parameter analyzer in a Lake-shore Cryogenic probe station under high vacuum (1 × 10⁻⁶ Torr) or in a Quantum Design PPMS.
